Myiasis is a temporary infection of the skin or other organs with fly larvae.1 The larvae develop into boil-like lesions. Creeping sensations and pain are usually described by patients. Following the maturation of the larvae, spontaneous exiting and healing is experienced. Herein we present a case of a traveler returning from Central African Republic. She does not recall insect bites. She never took off her clothing for recreational bathing, nor did she visit any rural areas. The lesions appeared on unexposed skin. The specific diagnosis was performed by morphologic characterization of the larvae, resulting in Cordylobia anthropophaga, the dominant form of myiasis in Africa. To our knowledge, this is the first reported case of C. anthropophaga in Latin America.

Introduction

Myiasis is a parasitic disease caused by the larval stages of dipterous flies.1 It is classified according to the infection site in cutaneous, urogenital, oral, ocular, and nasal. Cutaneous disease is the most common form,2 which is subdivided into three possible presentations based on clinical features and causative genus: furuncular, migrans, and wound myiasis.3 Cordylobia anthropophaga cases have been reported in travelers retuning from Africa in countries such as the United States,4 United Kingdom,5 Korea,6 and Portugal.7 Usually, C. anthropophaga produce multiple, subcutaneous, actively growing furunculous lesions, whereas Dermatobia hominis, in humans, produce only one.8 To our knowledge this is the first reported case of Cordylobia spp. in Latin America.

Case presentation

A 46-year old female presented to our clinic on September 11, with four swollen, non-painful boil-like lesions on her right lumbar and gluteal regions. The patient had been in Bangui, Central African Republic from August 13 to August 25, 2017. While on her flight to Geneva on August 25, she started feeling a stinging sensation...
on her right lumbar fossa, with no other associated symp-
toms. She did not recall any trauma or insect bites. Upon
arrival to Geneva she sought medical attention for increas-
ing pain and erythema in two well defined, non-elevated
nodular lesions on her right lumbar fossa and two other lesions
of similar characteristics on her upper right gluteal region.
A general practitioner prescribed an antihistamine agent and
referred her to a dermatologist. Upon her visit to the derma-
tologist, on August 30, the lesions had become warm, tender,
elevated, and suppurative. The dermatologist recommended
a 7-day regimen of trimethoprim-sulfamethoxazole and anal-
egesics. However, the symptoms did not improve. She traveled
to Panama on September 2. The following night, she woke up
in pain and noticed blood and a purulent discharge from the
lesions (see Fig. 1), along with one oval shaped, white “worm”
of approximately 1 cm in length that had emerged from one of
the aforementioned lesions. She visited a local emergency
room the morning of September 4, where the wounds were
occluded with petroleum jelly and three additional fly larvae
were extracted (see Fig. 2).

Upon examination in our clinic on September 11, she had
four round, erythematous, non-tender, 1.5 cm in diameter,
furunculous lesions with ulcerated centers on the right lum-
bar and upper gluteal areas. There was no evidence of bacterial
superinfection.

The rest of her medical history and physical exam were
non-contributory. She had no other recent foreign travel and
her immediate contacts were all well. She was on no regular
medication and had no known allergies.

Two days later, on September 13, she noticed a pale, non-
tender nodule on her lower vermilion border on the right side
of the lips. She was advised to apply petrolatum jelly to the
area. This nodule experienced involution over the next four
days. There was no evidence of larval presence in this lesion.

The original four lesions had resolved completely by
September 18.

The etiologic diagnosis was performed by morphologic
evaluation of the larvae (refer to Fig. 3). It was identified
as C. anthropophaga. Microscopic observation of the speci-
mens demonstrated whitish, 12 mm long segment larvae,
with the following features: imperceptible posterior tracheal
trunks, anterior spiracles with nine branches, posterior spir-
acles with three respiratory openings and no peritreme,
complete spine rings in segments III to VIII, and less pro-
nounced, non-chitinized spines in segments IX to XII.

Discussion

The genera involved in human myiasis infections are D.
hominis, which is the primary human botfly; Cochliomyia hom-
niorax, or the screwworm fly in the New World; Chrysomya
bezziana, or the screwworm fly in the Old World; and C.
anthropophaga. Some other flies in the genera Cuterebra, Oestrus
and Wohlfahrtia are animal parasites that occasionally infect
humans. The two most common species affecting humans are D.
hominis or the bot fly and C. anthropophaga or the tumbu fly. Transmission of D. hominis larvae is indirect: they lay
eggs on the surface of hematophagous arthropods, an inter-
action known as “phoresia”. When the carrier arthropod reach
man or animals, larvae leave eggs and penetrate the skin. Lit-
erature states that the dermatosis in Cordylobia spp. occurs
via biophagous intermediate larvae, since they oviposit over
damp clothing; and once hatched, 2–4 days later penetrate
fabric and skin without being noticed by the host. Larvae exit
the skin after 8–12 days. Furuncular myiasis is characterized
by painful nodules in the skin with circumscribed inflam-
mation of the dermis and subcutaneous tissue, enclosing a
central slough by which the mature larvae will emerge. Mul-
tiple lesions, each containing a single larva may be present,
especially with the tumbu fly.

The patients do not usually recall an insect bite, but do
notice a papule that slowly enlarges to become a painful
1–3 cm sized nodule. They also often describe a crawling
or creeping sensation. The pain is correlated with the para-
sites’ activity and lytic reaction. Scarce serosanguinous fluid
is consistently reported to drain from the lesions. Our patient
described a bloody and pus like discharge that stained
her bed sheets. This secretion includes larval excretions.
Treatment includes the occlusion of the lesions with dense
ointments, such as petroleum jelly, to provoke hypoxia and
the removal of the undamaged larvae. In rare occasions, surgi-
cal debridement is necessary. After the spontaneous exit of
the first larva, our patient had petrolatum jelly applied to the three
occupied lesions and three remaining larvae were extracted in
the emergency department.

Patients usually do not remember contact with adult flies.
This is consistent with the fact that adult flies are non-
parasitic and do not directly deposit eggs on human skin,
in contrast with D. Hominis that do oviposit directly on skin.
Zump, in 1965 described the adult flies as stout and compact,
Fig. 3 – Morphologic characterization of a Cordylobia anthropophaga larva that was extracted from one of the four lesions. (A) Third instar larvae of 12 segments, 10 mm length by 2.5 mm width. (B) Posterior spiracles with three curved respiratory openings without peritreme or button. (C) Cephalopharingeal skeleton: MS, mandibular sclerite strongly curved; HS, hipopharingeal sclerite; DH, dorsal horn with acute anterior process in the dorsal arc (DA). Averaging about 9.5 mm in length, light brown in color, with diffuse blue-gray patches on the thorax and dark gray on the posterior part of the abdomen, with yellow face and legs.

The adult female lays around 300–500 eggs in a lifespan and does so in two separate batches of about 100–300. Ova are preferably deposited in wet sandy soils or damped clothing, after which they hatch in 24–72 h. The first larval stage, or L1, could survive without nourishment for about nine days. The L1, from wet soil or fabric, attaches to skin by means of mandibular hooks. It is described that thinner skins are favored, such as those of children; nonetheless it affects all age groups. Two to four days pass before the second larval stage, L2, develops, and another one to three days before the third larval stage, L3, is formed. The fully mature instar, L3, naturally emerges off the skin at about 9–12 days, and it falls on the ground and pupates after another 12 days in tropical temperatures or up to 26 days at lower temperatures. In our patient, the time lapse between the onset of symptoms and the expulsion of the L3 was 10 days. Some important differences of C. anthropophaga when compared with D. hominis are summarized in Table 1:

Prevention strategies for travelers include drying their clothes hanging instead of placing them over a flat surface, ironing them before wearing, because heat is hypothesized to kill the larvae, and avoid being barefoot.

Even though our patient resides in an endemic country for D. hominis, she had been in Sub-Saharan Africa, and hence, suspicion for C. anthropophaga should have been raised from the beginning. Given the fact that Cordylobiasis has never been reported in our region, travel history and awareness of its existence were key elements in the diagnostic approach. To confirm the diagnosis, morphologic identification should always be carried out by an experienced entomologist.
