Abstract
Introduction: Hepatitis B virus (HBV) infection is an important worldwide public health problem. In Brazil, the Ministry of Health estimates that 15% of the population has had contact with HBV, and that the mean rate of chronic carriers in Northeastern Brazil is around 0.5%. Objective: The aim of this study was to assess the prevalence of HBV markers in pregnant women receiving prenatal care at the public maternity hospitals of São Luís. Methods: Demographical and epidemiological data were collected from 541 pregnant women according to the research protocol. Blood samples were collected, and the anti-HBc test was performed first. If positive, the sample was subsequently tested for HBsAg and anti-HBs. All HBsAg and/or anti-HBc positive samples were additionally tested for HBV-DNA. Results: 40 (7.4%) pregnant women turned out positive for anti-HBc. Of those, five (0.9%) were HBsAg positive, four (0.7%) were anti-HBc positive with negative HBsAg and anti-HBs, and 31 (5.7%) were positive for anti-HBc and anti-HBs. Anti-HBc positivity was associated with family history of hepatitis and education level below 11 years of schooling. HBV-DNA was positive in only one HBsAg-positive sample. There was no HBV-DNA positivity among HBsAg negative samples. Conclusions: The prevalence of HBsAg in pregnant women in this study confirmed that São Luís is a low endemicity area. Occult hepatitis B was not detected in these samples.

Introduction
The hepatitis B virus (HBV) is the most common cause of chronic infection worldwide, and can lead to liver cirrhosis and hepatocellular carcinoma (HCC). The prevalence of this infection varies widely in different parts of the world, with areas of high (more than 8%), medium (between 8% and 2%), and low endemicity (less than 2%). In Brazil, prevalence rates are heterogeneous; the Amazon region and part of some states of South and Southeast Brazil are considered areas of high and medium endemicity, respectively.
The Brazilian Ministry of Health estimates that 15% of the country population has been exposed to HBV, and that the average rate of chronic carriers in the capital cities of Northeast Brazil is approximately 0.5%, according to a national survey. HBV is transmitted by perinatal, parenteral, and sexual exposures. Perinatal transmission is of great importance in the epidemiology of the disease, since only 5% to 10% of those who acquire the infection in adulthood progress to chronicity. In contrast, children born to HBV infected mothers have a risk of chronicity of up to 90%. In pregnant women, there is little information about occult HBV infection, and it is still not well established whether prophylactic actions are needed to prevent infection in newborn children.

Results

541 pregnant women participated in this study. The mean age was 24 ± 5 years. Three hundred and sixteen (59%) reported having 11 or more years of schooling. 327 (61%) lived in a consensual union. Chronic HBV carriers were defined as pregnant women with positive total anti-HBc and HBsAg, longer than six months. Those with positive total anti-HBc and anti-HBs were considered as immune to HBV infection, and those with positive anti-HBc, negative HBsAg and positive HBV-DNA were considered as occult HBV infection carriers.

518 BRAZ J INFECT DIS. 2012;16(6) 517–520
undergone surgical procedures, and 205 (38%) had had some type of dental treatment. 120 (22%) reported to have a family history of hepatitis. 106 (20%) had had more than two sexual partners. Only one individual reported using injectable illicit drugs (Table 2).

40 patients (7.4%, 95% CI, 5.4% to 10%) were positive for anti-HBc total. Five (0.92%, 95% CI, 0.3% to 2.3%) were chronic carriers of the infection (HBsAg positive longer than six months), 31 (5.7%, 95% CI, 4.2% to 8.2%) were immune to HBV infection (positive anti-HBs), and four (0.8%, 95% CI, 0.2% to 2.1%) had isolated total anti-HBc positive.

Comparing the differences between the characteristics of groups with positive or negative anti-HBc it was observed that only the level of education and the presence of family history of hepatitis were statistically associated with the presence of a positive marker (Table 3).

Despite the presence of anti-HBs marker, all anti-HBc positive and HBsAg negative samples (n = 35) tested for HBV-DNA were negative. Thus, occult hepatitis B infection was not observed.

**Discussion**

Hepatitis B is a disease of significant public health impact. Prevention strategies are important for the effective control of this infection, including universal vaccination and the use of immunoglobulin in certain situations. For this purpose, data about prevalence rates are needed, especially in populations at risk for disease transmission, such as pregnant women.

No studies in the state of Maranhão on the prevalence of serological markers of HBV in any population could be retrieved. In this representative sample of pregnant women attending public services of São Luís, five patients had the marker of current HBV infection (HBsAg) and thus, a prevalence rate of 0.94% (95% CI, 0.3% to 2.3%), which is not different from most of the results found in studies conducted in other Brazilian states (ranging from 0.5% to 1.7%).8-11 and far below the prevalence found in a study in the state of Amazonas, which was as high as 8.7%.12 The prevalence found in the present study confirms the expectation that the state of Maranhão is a region of low HBV endemicity.

When comparing the characteristics of the groups with and without positive markers for HBV, it was observed that only family history of hepatitis and low level of education were positively associated. Family history could be explained by the possibility that some patients have family members with HBV infection, who could have transmitted the disease to them and then cleared the virus (remaining the markers of contact). Such occurrence is frequent after five years of age, which is already clearly shown in some regions of the world, including Brazil.20 Another explanation could be the possibility of episodes of acute infection in sexual partners, who may have transmitted the disease, with subsequent progression to cure. The level of education, probably a surrogate of low socioeconomic status, reflects poor knowledge about prevention as well as poor access to health services, which lead to greater susceptibility to infection.

Cases of occult hepatitis B among HBsAg negative and anti-HBc positive individuals were not identified, even among those who had isolated anti-HBc, without anti-HBs marker. This result was consistent with the expectation that this event is uncommon in areas of low endemicity, although this has already been described in the general population in Brazil.15

This study demonstrated the low prevalence of chronic HBV infection in pregnant women assisted in public maternity hospitals of São Luís. The presence of serological markers for HBV infection was associated with lower educational levels and family history of hepatitis. These results confirm that investments in education are important for the prevention of most diseases. The absence of cases of occult HBV is consistent with the area of low HBV prevalence expected for São Luís.
