ABSTRACT

Background: Data regarding Hepatitis B and C viruses (HBV and HCV) prevalence among military personnel in Brazil are lacking, but the work-related risk of exposure can be high. The objective of this study was to estimate the seroprevalence of HBV and HCV and the risk factors associated to HBV exposure among Brazilian military personnel.

Methods: A cross-sectional study was conducted and included 433 male military adults aged 18–25 years old working in Rio de Janeiro during October 2013. All individuals completed a questionnaire to assess their risk of exposure and provided a blood sample to HBV and HCV testing.

Results: None of the participants presented HBsAg or anti-HBc IgM, 18 (4.1%) were positive for total anti-HBc, 247 (57.0%) were positive for anti-HBs, and 3 (0.7%) were anti-HCV reactive. The majority of military personnel with past HBV infection (anti-HBc reactive) and HBV immunity (anti-HBs reactive) had a history of prior dental procedures (88.9% and 77.3%), consumption of alcohol at least once a week (50% and 55.9%), and practiced oral sex (61.1% and 58.3%, respectively). In addition, anti-HBc positivity was common among individuals with a history of surgery (44.4%) and practice of anal sex (50%). At univariate analysis, age group was associated to anti-HBc and anti-HBs positivity.

Conclusions: Low rates of HBV and HCV infection were observed among Brazilian military personnel in comparison to the general Brazilian population. HBV immunity rates were relatively low indicating the need for vaccination campaigns in this group.
**Introduction**

Hepatitis B and C viruses (HBV and HCV) share parenteral route as a common mode of transmission. Worldwide, approximately 240 million people are chronically infected with HBV and 130–150 million with HCV. A population-based multicentric, epidemiological survey was conducted in the general population across the five geographic regions of Brazil and found an overall HBsAg seroprevalence rate of 0.37%, 7.4% of anti-HBc, and 1.38% of anti-HCV among individuals aged 10–69 years.  

Prevalence studies of these blood-borne diseases showed certain risk groups and behaviors that should be considered as reasons for concern and taken into account when designing a more appropriate epidemiological investigation. In this context, anti-HBc reactivity has been reported to be 1.7% among health professionals, 5.9% among beauticians, and 12.8% among recyclable waste collectors. Anti-HCV seroprevalence has a narrower range: 0.2% among children, 1.3% among crack users, and 1.4% among truck drivers.

Young men are group in whom it is very important to recognize risk behaviors associated with parenterally transmitted diseases. Military personnel offer a reachable and often nationally representative sample for disease surveillance. In Brazil, military service is compulsory for one year for men aged 17–20 years from all social classes. Brazilian military personnel are being sent to countries that present high estimated prevalence rates for HBV and HCV infection, such as Colombia where HBV prevalence was 18.6%1 and Haiti with HCV prevalence of 4.4%. This group of individuals could be more exposed to transmissible infectious diseases due to their missions.

HBV immunization was included in the Brazilian vaccination schedule for newborns in 1996 and was also recommended to military personnel in 2010. In Brazil, the coverage of hepatitis B vaccination among children less than 18 months old varies from 80 to 95% according to socioeconomic status. Among young adult males in the Air Force in South Brazil, 84% of them reported a three-dose schedule of HBV vaccination while 66.9% of fire-fighters from Central Brazil had serum markers of HBV immunity. Thus, in face of the paucity of data regarding HBV and HCV markers of infection among military personnel in Brazil, this study was conducted to estimate the prevalence rates of HBV and HCV markers and risk factors in military personnel serving at a military unit in Rio de Janeiro City, in southeast Brazil.

**Methods**

**Study population**

This is a cross sectional, seroprevalence study and consisted of 433 military male personnel in the age range of 18–25 years old. All of them belonged to the largest military unit considered to be a central point for recruits and officers education in Rio de Janeiro State and one of the oldest units of Brazil. In this unit, approximately 1200 individuals are serving in the Military, the majority of them being conscripts.

In Brazil, military service is compulsory and young men have to draft for serving in the armed forces, most of them in the Army, when they turn 18, independent of level of education or socio-economic status. After concluding the recruitment process, those conscripts who were considered suitable by a selection commission begin basic military training at different military units. Those willing to pursue a military career will remain in service.

The recruitment for this study was began in October 2013 and all individuals serving at the aforementioned unit were invited to participate in the study soon after their arrival to that military unit. Study participants were male, aging 18 years or more, and registered in the military service. Those not consenting to participate were excluded.

**Questionnaire**

A standard questionnaire was submitted to the study subjects by the team of this study before blood collection. The questionnaire inquired about socio-demographic characteristics of the individuals (age, gender, educational status, income level, history of previous hepatitis) and risk factors for hepatitis B and C [history of blood transfusion or blood products, surgery, intravenous drug use, haemodialysis, dental procedures, acupuncture, tattooing, piercing, alcohol consumption at least once per week, sexually transmitted diseases (STDs), sexual orientation, number of sexual partners, condom usage, practice of oral and/or anal intercourse, exposure to manicure/pedicure who used non-sterilized instruments, and sharing personal care items such as toothbrushes, razors/blades, nail clippers or scissors].

Information on HBV vaccination (vaccination status and number of doses received) was collected through a self-report method since vaccination cards or medical charts were not available for consultation at the time of enrolment into the study.

**Blood sampling for detection serological markers of viral hepatitis**

A blood sample (5 mL) was taken from each subject by venipuncture using a vacutainer device. The sample was allowed to clot for serum recovery and stored at –20 °C until analysis.

Serum samples were tested for HBsAg, anti-HBc IgM, total anti-HBc, anti-HBs, and anti-HCV using commercial enzyme-immunoassay (ELISA) kits (Diaisorin, Italy), according to the manufacturer’s instructions. Samples found to be negative on the preliminary screening were considered seronegative and samples initially tested borderline or positive were retested using the same assay in order to confirm these results.

**Data collection and analysis**

The prevalence rates of HBV and HCV markers were calculated for the total study population. Continuous variables were reported as the mean ± standard deviation. Descriptive statistics were generated for the responses, and the chi-squared test (χ²) for independence or for trend was used to assess the association of categorical variables and anti-HBc and
results for HBV infection in Brazilian military personnel. The prevalence of HBV infection was 41.8% in this population, which is lower than the prevalence reported in other studies in Brazil. The most prevalent risk factors for HBV infection were injection drug use (61.1%), tattooing (55.9%), piercing (59.1%), and oral sex (77.3%). The study also found that the prevalence of HBV infection was higher among individuals with a lower education level and lower income. The results suggest that interventions targeting these risk factors may be effective in reducing the prevalence of HBV infection in Brazilian military personnel.

Discussion

The results of this study highlight the importance of targeted interventions to reduce the prevalence of HBV infection in Brazilian military personnel. The high prevalence of HBV infection in this population is a significant public health concern, and efforts to reduce the prevalence of HBV infection should be a priority. The findings of this study also suggest that interventions targeting high-risk behaviors such as injection drug use, tattooing, and piercing may be effective in reducing the prevalence of HBV infection in Brazilian military personnel. These findings have important implications for public health policy and practice in Brazil, and they should be considered when developing interventions to reduce the prevalence of HBV infection in this population.
HBV immunity, probably due to the inclusion of HBV vaccination in childhood immunization program, since most of individuals were young. The same rate of HBV immunity was observed among air force personnel from South Brazil, but this rate is lower than the rate reported among Saudi Arabia soldiers (57.5%), fire-fighters from Central Brazil (66.9%), Spanish military personnel (78.3%).

Nowadays the coverage of hepatitis B vaccination among children less than 18 months of age varies from 80 to 95%, but the low prevalence of HBV immunity observed in the present study is probably due to the fact they were the first generation of compulsory vaccination.

A person is considered immune to HBV when anti-HBs levels are equal or greater than 10 mIU/mL in serum, which may be acquired through HBV infection or post vaccination. Ninety-eight percent of infants achieve seroprotection after HBV vaccination with a three-dose schedule. However, after completion of the vaccine schedule, anti-HBs titres decline and may fall below this threshold, sometimes to undetectable levels. In the present study, 32.1% of individuals reported previous HBV vaccination but only 7.4% of them had completed the schedule, and 21.0% of them presented anti-HBs reactivity (anti-HBs levels equal or greater than 10 mIU/mL in serum). HBV immunity rates may be 21.0% among those who reported a 3-dose schedule, 32.1% among those who reported HBV vaccination and 57% considering those with detectable anti-HBs. These results show the importance of anti-HBs testing in order to confirm HBV immunity since self-reported vaccination could not be confirmed.

Military personnel are more exposed to transmissible infectious diseases due to their missions. These individuals are far from home and exposed to several infectious agents what could have an impact over virus heterogeneity since they can import new variants. These professionals may serve as a source of infection, especially for STD since military installations usually attract gatherings of sex workers.

In the present study, no conscript were positive for HBsAg or anti-HBc IgM markers while HBsAg prevalence was found to vary from 0.3% among Greek military recruits, 2.8% among Turkish recruits, and 4% among Saudi Arabia soldiers. The finding that all individuals in the present study tested negative for HBsAg could be explained, at least in part, by the age less than 25 years of most study subjects. HBV vaccination was became part of the vaccination schedule to all newborns in Brazil in 1996 and was extended to individuals aged up to 20 years in 2001.

HBV past infection was observed in 18 (4.1%) young military males, a frequency lower than that observed among Saudi Arabian soldiers (13.2%) but higher than that reported among military personnel from Greece (1.68%), and Spain (0%). Anti-HBc reactivity was associated with age-group. The same was observed among recyclable waste collectors, indicating that over time, there is a greater trend of acquiring HBV infection related to sexual and parenteral exposures.

Anti-HCV prevalence was 0.7% among Brazilian military personnel, a prevalence similar to that reported by studies conducted among Afghan National Army recruits (0.8%) and Peruvian Air Force, (0.2%), but this rate was lower than that documented among Pakistan Military Force (3.13%). Anti-HCV prevalence among Brazilian military personnel was lower than the rate (1.38%) reported for the general Brazilian population and suggests that conscripts are not under higher risk for HCV infection. In addition, most anti-HCV positive individuals reported previous intravenous drug use, suggesting that this risk factor could be the mode of transmission in this small group of conscripts. Our results reinforce the need for education programs in order to avoid risk practices for HCV acquisition in this population.

The present study presents some limitations. First, it may be affected by selection bias, as the participants were predominantly healthy young adult males. Therefore, the results cannot be extended to the Brazilian general population or to special populations at high risk for HBV and HCV infection.
such as intravenous drug users, sex workers, and hemodialysis patients. Second, validity of self-reporting data such as HBV vaccination and history of viral hepatitis might be compromised by recall bias since these informations were not obtained by consulting the conscripts’ records. Since anti-HBs levels could decline over time in vaccinated individuals, it is possible that some conscripts with undetectable levels of anti-HBs have already been, in fact, vaccinated.

Finally, vaccination programs are important in this group, since these individuals are more exposed to viral infections during their duties. In this context, they can play an important role on virus epidemiology either by importing or exporting HBV variants.

Conclusion

In conclusion, this study shows a low prevalence of HBV and HCV infection among Brazilian military personnel, reflecting the success of universal immunization toward the eradication of HBV transmission. The rate of HBV immunity was relatively low in this group indicating the need for vaccination campaigns targeting these professionals and the importance of prevalence studies for HBV and HCV infection in order to design effective prevention and control programs.

Conflicts of interest

The authors disclose no current or potential conflict of interest, including any financial, personal or other relationships with people or organizations, within two years of the beginning of this study that could inappropriately influence the study.
