ABSTRACT

Background: Candidemia is the most frequent invasive fungal disease in hospitalized patients, and is associated with high mortality rates. The main objective of this study was to evaluate changes in the epidemiology of candidemia at a tertiary care hospital in a 21-year period.

Methods: We evaluated all episodes of candidemia diagnosed between 1996 and 2016 at a University-affiliated tertiary care hospital in Brazil. We arbitrarily divided the study period in 3: 1996–2002 (period 1), 2003–2009 (period 2) and 2010–2016 (period 3). Incidence rates were calculated using hospital admissions as denominator.

Results: We observed 331 episodes of candidemia. The incidence was 1.30 episodes per 1000 admissions, with no significant change over time. Candida albicans (37.5%), C. tropicalis (28.1%), C. parapsilosis (18.4%) and C. glabrata (6.9%) were the most frequent species. The proportion of patients receiving treatment increased (65.5%, 79.4% and 74.7% in periods 1, 2 and 3, respectively, p = 0.04), and the median time from candidemia to treatment initiation decreased from 4 days in period 1 (range 0–32 days) to 2 days in period 2 (range 0–33 days) and 2 days in period 3 (range 0–14 days, p < 0.001). We observed a significant decrease in the use of deoxycholate amphotericin B (47.4%, 14.8% and 11.9%), and an increase in the use of echinocandins (0%, 2.8% and 49.1%; p < 0.001). The APACHE II score increased over time (median 16, 17.5, and 22, p < 0.001). The overall 30-day mortality was 58.9%, and did not change significantly over the study period.

Conclusions: There was an improvement in patient care, with an increase in the proportion of patients receiving treatment and a decrease in the time to treatment initiation, but no improvement in the outcome, possibly because the proportion of sicker patients increased over time.

**Introduction**

Candidemia is a serious bloodstream infection, with incidence rates between one and three episodes/1000 admissions, and crude mortality rates exceeding 40% in Brazilian tertiary care public hospitals.\(^1\)\(^-\)\(^9\) Epidemiologic studies conducted in the region have shown that *Candida albicans*, *Candida tropicalis* and *Candida parapsilosis* account for over 80% of episodes of candidemia, and *Candida glabrata* accounts for less than 10% of cases in public hospitals.\(^1\)\(^-\)\(^3\) However, in private hospitals the incidence of candidemia due to *C. glabrata* is higher,\(^10\)\(^-\)\(^11\) and a trend for an increase in the incidence in one public hospital has been reported.\(^12\)

Over the past 15 years, changes in the epidemiology of candidemia have been documented, including shifts in species distribution,\(^13\) changes in patterns of resistance\(^14\) and therapeutic practices, with an increase in the use of echinocandins as primary therapy.\(^3\) In this study we sought to evaluate changes in the epidemiology of candidemia at a tertiary care teaching public hospital in Brazil over the course of two decades.

**Patients and methods**

We conducted a retrospective study at University Hospital, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil. This is a tertiary care hospital with 450 beds with different medical and surgical specialties, and admits patients older than 12 years. We evaluated all episodes of candidemia diagnosed in the hospital from January 1996 to December 2016. The study was approved by the local Ethical Committee (number 30/03). Since 2010 there was a reduction in the overall number of beds in the hospital. However, the epidemiologic profile of patients did not change in the study period. Throughout the study period the decision of the choice of the antifungal drug for the treatment of candidemia and catheter management were at the discretion of the attending physicians.

An episode of candidemia was defined as the first isolation (incident candidemia) of *Candida* species from a blood culture in a patient with signs of infection. If a new blood culture was positive within 30 days from the day of the incident candidemia, it was considered part of the same episode. However, if there was a new positive blood culture that was obtained beyond 30 days from the incident candidemia, this new positive blood culture was considered as a new episode of candidemia.

A case of candidemia was identified by looking at the records of the microbiology laboratory. Once a case was identified, patients were followed for 30 days from the date of the incident candidemia. All data were collected prospectively, using a standardized case report form, with the help of a dictionary of terms containing all definitions of the variables collected. The following data were collected: age, gender, date of hospitalization, medical ward, underlying medical condition, co-morbidities (liver, lung, cardiac, neurologic or renal disease), receipt of transplant, hemodialysis, parenteral nutrition, mechanical ventilation, surgery (of any type requiring any anesthesia other than local anesthesia within the 3 months prior to the incident candidemia), neutropenia (<500 neutrophils/mm\(^3\)), central venous catheter (CVC), receipt of corticosteroids, H2 blockers, antibiotics or antifungal agents (in the previous 2 weeks), APACHE II score on the day of the incident candidemia, hypotension or receipt of vasoactive agents in the previous 2 days, fever, antifungal treatment, and the outcome (alive or dead 30 days after the incident candidemia).

Blood cultures were collected by clinical indication, and processed using the automated system Bactec (Becton Dickinson, NJ, USA) in 1996 and 1997, and BactAlert (bioMérieux, Marcy-l’Etoile, France) from 1998 to 2016. Isolates were identified according to their microscopic morphology on cornmeal TWEEN 80 agar, complemented by biochemical tests using the ID 32C system (bioMérieux AS, Marcy l’Etoile, France) or Vitek 2 cards (bioMérieux AS, Marcy l’Etoile, France).

In order to evaluate epidemiologic trends of candidemia, we arbitrarily divided the 21-year study period in 3: 1996–2002 (period 1), 2003–2009 (period 2) and 2010–2016 (period 3). In the analysis, we defined three age categories: children (<18 years), adults (19–59 years) and elderly (≥60 years). Incidence rates were calculated using hospital admissions as denominator. Comparisons of categorical variables were undertaken using Fisher or Chi-square test as appropriate, and for continuous variables we used the Kruskal–Wallis test. The incidences of candidemia in the three periods were compared by the chi-square test for trend. P values <0.05 were considered statistically significant. All statistical analyses were performed in the SPSS software (version 15, SPSS, Inc.).

**Results**

During the study period we observed 331 episodes of candidemia in 324 patients. The median age of the 324 patients was 56 years (range 12–92), and 52.7% were males. The overall incidence of candidemia was 1.30 episodes per 1000 admissions, and did not change significantly in the three study periods: 1.05 per 1000 admissions in period 1, 1.50 in period 2, and 1.38 in period 3 (p = 0.58).

Table 1 shows the characteristics of the 331 episodes in the three study periods. The median age increased slightly over time, from 52.5 years in period 1 to 56.5 years in period 2 and 60.5 years in period 3 (p = 0.06). On the other hand, there was a statistically significant increase in the APACHE II score over time (16, 17.5 and 22, in periods 1, 2 and 3, respectively, p < 0.001). Other significant changes comparing periods 1, 2 and 3 included an increase in the proportion of patients with chronic renal failure (p = 0.02), cardiac disease (p = 0.03), receiving dialysis (p = 0.003), corticosteroids (p < 0.001), vasoactive amines (p < 0.001), and on mechanical ventilation (p = 0.02). The proportion of patients with liver disease increased from period 1 to 2 and decreased in period 3 (p = 0.02). Of note, the proportion of patients in intensive care unit (ICU) did not change significantly.

The most frequent etiologic agent of candidemia was *C. albicans* (124 episodes, 37.5%), followed by *C. tropicalis* (93 episodes, 28.1%), *C. parapsilosis* (61 episodes, 18.4%) and *C. glabrata* (23 episodes, 6.9%). The remaining 30 episodes were caused by *C. pelliculosa* (7 episodes), *C. krusei* and *C. famata*.
shows the antifungal agents used as primary distribution during the three periods (6 episodes each), C. guillermondii (5 episodes), C. kefyr (3 episodes), and C. zeylanoides, C. lipolytica and Pichia ohmeri (1 episode each). There was no significant difference in species distribution during the three periods (Table 1). Previous exposure to fluconazole was associated with a higher proportion of candidemia due to C. glabrata or C. krusei (20.7% with vs. 9.7% without previous exposure to fluconazole), but the difference was not statistically significant (p = 0.10 and p = 0.06, respectively).

Table 2 shows the antifungal agents used as primary therapy of candidemia. Overall, antifungal treatment for candidemia was given in 243 episodes (78.1%). The proportion of patients receiving treatment in periods 1, 2 and 3 was 65.5%, 79.4%, and 74.7%, respectively (p = 0.04). Among patients who received treatment, the median time from the date of the incident candidemia to the start of antifungal therapy reduced from 4 days in period 1 (range 0–32 days) to 2 days in period 2 (range 0–33 days) and 2 days in period 3 (range 0–14 days, p < 0.001). Primary therapy differed significantly in the three periods, with a sharp reduction in the use of deoxycholate amphotericin B (47.4% in period 1, 14.8% in period 2 and 11.9% in period 3), an increased use of echinocandins (0% in period 1, 2.8% in period 2 and 49.1% in period 3), whereas the use of azoles increased in period 2 (from 48.7% to 64.8%) and decreased in period 3 (39.0%, p < 0.001).

Patients who did not receive treatment were more likely to be older (61 years, range 15–92 vs. 56 years, range 11–92, p = 0.03), to have renal failure (60.2% vs. 46.1%, p = 0.02), solid tumor (28.4% vs. 16.0%, p = 0.01), to be on mechanical ventilation (55.7% vs. 41.2%, p = 0.02), hypotensive (69.3% vs. 51.5%, p < 0.001), to receive vasoactive drugs (59.1% vs. 31.7%, p < 0.001). By contrast, no treatment was less frequent in candidemia due to C. glabrata (15.9% vs. 3.7%, p < 0.001). By contrast, no treatment was less frequent in candidemia due to C. glabrata (15.9% vs. 3.7%, p < 0.001). By contrast, no treatment was less frequent in candidemia due to C. glabrata (15.9% vs. 3.7%, p < 0.001).

OVER THE COURSE OF THE THREE PERIODS, WE OBSERVED SOME IMPORTANT IMPROVEMENTS IN PATIENT CARE, INCLUDING A HIGHER PROPORTION OF PATIENTS RECEIVING TREATMENT, A SHORTER TIME BETWEEN THE DATE OF THE INCIDENT CANDIDEMIA AND THE INITIATION OF THERAPY, AND AN INCREASE IN THE USE OF ECHINOCANDINS, WHICH IS ASSOCIATED WITH BETTER OUTCOMES. THESE IMPROVEMENTS SHOULD HAVE RESULTED IN A DECREASE IN 30-DAY MORTALITY. HOWEVER, THE MORTALITY RATE DID NOT DIFFER OVER TIME (59.5%, 57.4% AND 60.8% IN PERIODS 1, 2 AND 3, RESPECTIVELY). THE MOST LIKELY EXPLANATION FOR THIS OBSERVATION IS THAT THESE IMPROVEMENTS IN PATIENT CARE MAY HAVE BEEN COUNTERBALANCED BY THE FACT THAT OVER TIME THE PROPORTION OF SICKER PATIENTS INCREASED, AS SHOWN BY AN INCREASE IN THE MEDIAN APACHE II SCORE AND IN THE PROPORTION OF PATIENTS UNDER MECHANICAL VENTILATION, HYPOTENSIVE, AND RECEIVING VASOACTIVE DRUGS.

ALTHOUGH THE PROPORTION OF PATIENTS RECEIVING TREATMENT INCREASED, BETWEEN 20 AND 25% OF PATIENTS STILL DO NOT RECEIVE TREATMENT. AN ANALYSIS OF THE CHARACTERISTICS OF THESE PATIENTS SUGGESTS THAT THESE ARE VERY SICK PATIENTS, WITH HIGH APACHE II SCORES, ON MECHANICAL VENTILATION AND VASOACTIVE DRUGS. INDEED, THE MAJORITY OF UNTREATED PATIENTS DIED (85.2%), AT A MEDIAN OF TWO DAYS FROM THE INCIDENT CANDIDEMIA. THESE DATA SUGGEST THAT BY THE TIME BLOOD CULTURES BECAME POSITIVE THE

patient was already dead. Interestingly, 13 patients did not receive treatment and survived. The large majority (9 episodes, 69%) occurred in period 1, and only one in period 3. Over the past 15 years many changes have occurred in the care of candidemia, including active laboratory-based search for cases of candidemia, consulting and educational measures. These measures may have contributed to better patient care.

The overall mortality in the present series was high (58.9%), with an increase in death rate in the three age strata. Compared to large series published in the region, our mortality rate was much higher. This may be explained by the fact that the median age in the present study (56 years) was higher than in other studies (41 years in the second Brazilian study,1 and 26 years in the Latin American study7), because while in other studies patients from all ages (including neonates) were enrolled, our study was conducted in a hospital that admits only patients older than 12 years.

Our study has some limitations. While data were collected prospectively, the retrospective analysis was limited to the variables already collected. Likewise, there was some heterogeneity in the methods for processing blood cultures and species identification.

In conclusion, the incidence and species distribution of candidemia was similar to other studies conducted in Brazil, and did not change significantly over the 20-year period. There was a change in therapeutic practices, with a decrease in the time to treatment initiation and a change in primary therapy, from deoxycholate amphotericin B and fluconazole to an echinocandin. However, the 30-day mortality rate did not change, possibly because the proportion of sicker patients increased over time.
